ABSTRACT

Aim: To demonstrate an algorithmic approach to hypospadias repair with the aid of the surgical microscope as a teaching aid, as well as an ergonomic tool. Methods: One hundred and two patients were operated on between 2009 and 2013, all by the senior surgeon (M Dalal). This is a retrospective review of results in the case series. The procedures used were one stage repair with no incision of the urethral plate, or the two stage Bracka repair. Results: Fifty-six patients underwent the one stage procedure and 46 patients underwent the two stage Bracka repair. Early complication rate was 4.9% (n = 5) and late complication rate was 10.7% (n = 11). The fistula rate specific to one stage and two stage procedures was 5.3% (n = 3) and 13% (n = 6) respectively. Conclusion: A structured approach to hypospadias surgery will aid the surgeon in choosing the appropriate procedure for the appropriate patient. The authors have chosen to use 2 types of repair for all hypospadias subsets based on the algorithm. They find the microscope an invaluable teaching aid, whilst at the same time providing an ergonomic benefit, and providing a wide range of surgical site magnification.

INTRODUCTION

Hypospadias surgery has been performed for decades and centuries. It has evolved quite rapidly and there have been many procedures described along with their modifications. It remains a relatively common condition, occurring in 1:300 live births.¹

Hypospadias is characterised by the presence of an abnormally sited ventral urethral meatus, a dorsally hooded prepuce, and varying degree of penile ventral curvature “chordee”. The main aspect in its diagnosis is the abnormal position of the ventral urethral meatus, and to many, this position is related to complexity of the case and the type of repair chosen; when in fact there are other associated morphological aberrations that should be taken into consideration when considering repair. Common meatal positions are distal penile 70%, mid-penile 10%, and proximal types 20%.² We follow an algorithm, which helps in choice of repair irrespective of the meatal site. The surgical procedure in itself requires magnification and a bloodless field to execute a successful repair.
METHODS

One hundred and two patients were operated upon between 2009 and 2013; the senior author (M. Dalal) performed all patients. Inclusion criteria included primary hypospadias in the paediatric population irrespective of age at the time of initial presentation in clinic. Exclusion criteria, was 1 adult with delayed presentation of primary hypospadias, and 5 cases of phimosis, thought to have concealed hypospadias, treated with circumcision only. The following steps are common to both one stage and two stage procedures.

All patients were subjected to a general anaesthetic augmented with a caudal block; for prolonged postoperative pain relief. After induction, co-amoxiclav antibiotic (Augmentin-GlaxoSmithKline) at a dose of 30 mg/kg is given intravenously over 3-4 min. Medical photography after obtaining the consent from the parents is a routine part of our practice. The photographs are taken in 2 views once the patient is covered in surgical drapes.

The foreskin is retracted and all the smegma removed with a swab soaked in aqueous chlorhexidine, after which the surgeon exchanges the gloves to commence surgery. A urethral dilator size 6/8-8/10 is passed after lubrication to ensure that there is an adequate urethral calibre. A polypropylene 5-0 suture (Prolene-Ethicon) is passed on the dorsal surface of the glans for retraction. An 8 French (Fr) urethral catheter is secured at the base of the penis with a haemostat as a tourniquet to facilitate a bloodless field. The microscope (Carl Zeiss Microscopy GmbH) microscope is brought into the field at this stage to aid in visualizing the anatomical landmarks as well as carrying out the procedure under ×3.5-×6 magnification. A fine nib quill and ink are used to mark the incision lines, the markings for which differ between the one and two stage procedure. After the finishing the surgery, the suture line is covered soft non-adherent paraffin impregnated gauze (Jelonet-Smith & Nephew) and sandwiched on the child’s abdomen between two layers of low-adhesive perforated plastic films (Melolin-Smith & Nephew). This is further secured with a broad sheet of adhesive tape (Mefix-Mölnlycke Healthcare). The same adhesive tape is then used to secure the catheter and the paediatric urine bag. This dressing is left undisturbed for 1 week.

Post-operatively patients are kept on oral co-amoxiclav (Augmentin-GlaxoSmithKline) 0.25 mL/kg of 125/31 suspension 3 times daily for ages up to 1 year of age and 5 mL of 125/31 suspension 3 times daily for children older than 1 year. Oxybutynin is administered to prevent bladder spasm, at a dose of 1.25-2.5 mg, 3 times a day. Both medications are continued until the catheter is removed at 1 week post-operatively. Analgesics are given as and when required. We aim to discharge patients on the second post-operative day. They are reviewed at 1 and 2 weeks postoperatively. They then are reviewed at 3 months, and from then on yearly till school age.

One stage repair (without urethral plate incision)

A subcoronal marking is made on the dorsal penile surface and is continued ventrally to the edge of the urethral plate. The ventral markings are made all around the edges of the urethral plate and around the anomalous urethral opening in a “U” shaped design. The ventral incision is made around the urethral plate, and care is taken when dissecting the ventral skin off the anomalous urethral opening, as the corpus spongiosum is deficient, and there is a chance of injury to the urethra. The use of a urethral dilator to guide this part of the dissection can be very helpful. Ventral chordee encountered at this stage is corrected by degloving the penis. Glans flaps are dissected off the corpora cavernosa with a number fifteen Beaver blade (Beaver Visitec), to achieve a tension free ventral repair over the reconstructed neo-urethra. The dorsum of the penis is degloved in the sub-Dartos plane, and...
a thin Dartos fascia flap is dissected starting at the
distal end of the inner layer of preputal skin. Care is
taken to carry the dissection proximally with adequate
length in a manner that will allow tension free ventral
transposition after neo-urethral reconstruction. This
avoids rotation of the penis.

At this stage, a silastic size 6 Fr catheter is passed in
the urethra and 1.5 mL of distilled water is used inflate
the balloon. The penis is retracted cephalad to allow
for the reconstruction of the neourethra. The first step
of the reconstruction is to form the distal most part of
the neourethra with a single interrupted polyglactin 7-0
suture (Vicryl-Ethicon) around the inserted catheter.
This produces a natural slit like urethral opening. The
neourethra is then created starting at the edge of the
anomalous ventral meatus and is carried distally with
a running submucosal polyglactin 7-0 suture (Vicryl-
Ethicon) using the native urethral plate. In contrast with
the tabularized incised plate (TIP) procedure described
by Snodgrass, the urethral plate was not incised in all
of the patients but one. The width of the urethral plate
is not routinely measured, but in general, it has to be
sufficient to tubularise around the catheter chosen.
This varies according to patient age, penis size, and
the native urethral plate width; this is left to the clinical
judgement of the senior author, hence the steep
learning curve associated with hypospadias surgery.

A second layer from the soft tissue surrounding the
neourethra is used to reinforce the reconstruction,
and help create the deficient corpus spongiosum. It is
repaired using the same suture material in a running
fashion from proximal to distal. The competency of
the neourethra reconstruction is tested with an intra-
urethral injection of normal saline via a 22G intra-
venous cannula (BD Venflon), to delineate possible
leakage sites, which if found, are repaired using
interrupted sutures. Care is taken to introduce the
cannula dorsal to the urethral catheter to avoid injury
of the neo-urethra. The previously dissected Dartos
flap is transposed ventrally to create a waterproof
layer with its distal extent at the level of the coronal
sulcus. The Dartos flap is secured with interrupted
polyglactin 7-0 sutures (Vicryl-Ethicon). The flap is not
used in the distal (glandular and coronal) subset of
metal openings, as it would create an unwanted and
unnatural bulk under the glans flaps. The glans flaps
are brought together with an undyed polyglactin 6-0
suture (Vicryl-Ethicon).

The tourniquet is released at this stage and bleeding
vessels are cauterized with bipolar diathermy. After
haemostasis is secured the tourniquet is reapplied.
The ventral skin is closed in a “V-Y” manner starting
distally, where the ventral skin is sutured to the glans
flap with a four corner rapidly dissolving polyglactin 7-0
suture (Vicryl Rapide-Ethicon) at the frenulum. The
remainder of the ventral vertical limb is closed with
an interrupted suture using the same material. The
excess preputal skin is marked for excision. A number
15 Beaver blade (Beaver-Visitec) is used to make the
initial incision and the rest of the excision is carried
out with the bipolar diathermy to facilitate a bloodless
wound edge, which can be a source of postoperative
bleeding in circumcision. Care is taken when closing
the subcoronal incision to avoid a rotational deformity.
The average time taken for the one stage is between
60-75 min.

**Two stage Bracka repair**

The penis is examined under magnification and
the morphological findings are processed through
the algorithm, at which stage it will indicate that a
single stage repair is not suitable. With the two stage
approach, there is generally a deficiency of tissues to
form a neourethra and coverage.

The glans cleft in the centre of the narrow urethral

skin

---
plate is incised vertically with horizontal extensions at the meatus; and glans flaps are raised. A full thickness skin graft is harvested from the inner surface of the dorsally hooded prepuce, its dimensions are not routinely measured, and however, the overall width of the urethral plate and skin graft should be at least 12 mm. The donor is closed primarily using rapidly dissolving polygactin 7-0 suture (Vicryl Rapide-Ethicon). The skin graft is secured to the defect created using polygactin 7-0 sutures (Vicryl-Ethicon). The same suture material is used to quilt the skin graft. Polypropylene 6-0 sutures (Prolene-Ethicon) are used to secure the non-adhesive bolster dressing applied to the skin graft. A size 6 Fr silicone Foley’s catheter is inserted at this stage. The average time for the first stage is 45 min.

The second stage is performed for the patient 6 months after the first stage, where the graft has healed completely and the tissues have become soft and supple. The second stage is identical to the one stage repair, where by the lateral incisions are performed at the edge of the full thickness skin grafts. The average time taken is similar to the one stage repairs: 60-75 min.

**RESULTS**

A total of 102 patients were operated upon between 2009 and 2013. Inclusion criteria included primary hypospadias in the paediatric population. Exclusion criteria, was 1 adult with delayed presentation of primary hypospadias, and 5 cases of phimosis, thought to have concealed hypospadias, treated with circumcision only. Of the 102 patients, 56 underwent a one stage procedure while 46 underwent a two stage procedure. Mean age at presentation was 22 weeks ± 29.75 (SD). The mean age at surgery was 25 months ± 11.56 (SD).

Of the 102 cases, 41.2% (n = 42) were subcoronal, 20.6% (n = 21) coronal, 13.7% (n = 14) glandular, 1% (n = 1) terminal, 11.8% (n = 12) distal shaft, 2.9% (n = 3) mid-shaft, 3.9% (n = 4) proximal shaft, and 4.9% (n = 5) penoscrotal [Figure 3].

Early complications were those encountered within 6 weeks of the operative procedure, whilst any complication encountered after that period would be classed as a late complication. Early complication rate was 4.9% (n = 5) and they included dislodged/snapped catheters 1.9% (n = 2), wound dehiscence and infection 2.9% (n = 3). Overall late complication rate was 10.7% (n = 11). The most common complication was urethro-cutaneous fistula occurring in 8.8% (n = 9). The fistula rate specific to one stage and two stage procedures was 5.3% (n = 3) and 13% (n = 6) respectively. Other late complications included, altered urine stream 0.9% (n = 1) and urethral stricture 0.9% (n = 1) [Figure 4]. No complications related to bleeding were encountered. Re-operation was required for 2 patients with wound dehiscence and 9 patients with fistula.

**DISCUSSION**

Many techniques and modifications have been described for the repair of hypospadias, yet there has been no general consensus on a specific procedure for a given subset of hypospadias meatal positions or morphology. Prat et al.[3] published a series that covered three decades including 820 patients, highlighting different techniques and overall results. They performed meatal advancement and glanduloplasty (MAGPI), TIP, two stage procedures, onlay tabularised island flap, yet with a high incidence of complications. We employ the use of a simple double-armed algorithm ending in two procedures, which we feel are adequate to address treatment of hypospadias.

The algorithm [Figure 5] disregards the meatal position, and addresses other morphological findings; chordee, adequacy of the urethral plate, glans cleft, and presence of a urethral bar. A similar algorithm was utilised by Coleman et al. [4] whereby they used...
their algorithm to arrive at a choice of a one or two stage repair.

Chordee was present in 94.1% \((n = 96)\) of our patients with varying degrees; mild 81% \((n = 78)\), moderate 7% \((n = 7)\), severe 12% \((n = 11)\). In the presence of mild to moderate chordee and adequate urethral plate, adequate glans cleft, and a thin or no horizontal bar within the urethral plate, a one stage repair (Snodgrass type without urethral plate incision) is used. This procedure was initially described as TIP.\(^8\) We found no need to incise the urethral plate in all but 1 patient.

Adequacy of the urethral plate is based on the fact that it will be tubularised around a 6 Fr urinary catheter, as is standard in our practice. A urethral plate of 8-10 mm or more is sufficient for tubularisation without the need for augmentation. If the findings are not in favour of a one stage procedure as per algorithm, then a two stage Bracka repair is used.

The microscope was used for all the hypospadias repairs in our series. We found that its use was quite ergonomic, when surgeons were sat in an upright posture with relaxed shoulders and elbows rested on the operative table; this is important for surgeons who will be doing hypospadias surgery regularly. The microscope used also had a separate video screen; this displayed a view of the operative field as seen by the surgeons. This is an invaluable teaching aid, as often there may be a second assistant that will not be able to see the filed in the absence of this screen. Not only did the microscope serve an ergonomic and teaching purpose, but also provided magnification and illumination required for surgery on delicate and small structures, where along with appropriate microsurgical instruments are hallmark to a meticulous repair. Wacksman reported that the use of the microscope has allowed for the use of small fine sutures with great accuracy translating into results.\(^6\) Wesson \textit{et al.}\(^7\) found that it was a very useful teaching aid for residents. Unscrubbed junior colleagues observing will also be able to chronologically follow the surgical steps, to better understand this type of surgery, which does have a steep learning curve. It is also of note that other healthcare staffs in theatre are aware of the nature of the surgery that is being performed, and to able to identify what stage of the surgery has been reached at any given time.

Gilbert \textit{et al.}\(^8\) demonstrated that they experienced fewer complications when using the microscope. The non-microscope group had 17 complications, 12 of which required reoperation (24%), while the microscope group had 8 complications of which 4 required reoperation (6.5%). A head mounted microscope has been utilized in hypospadias surgery, again noticing a decrease in complications.\(^9\) Although this may provide magnification, there is no evidence to prove that it is more ergonomic than the surgical microscope.

In the 102 patients in our case series, 56 had one stage repairs while 46 had two stage Bracka repairs. Postoperative edema was not observed in any of our cases. Bhat and Mandal\(^10\) found that edema was the second most common early complication after hypospadias surgery. Urethro-cutaneous fistula remains the most common complication encountered by all. Snodgrass reported fistula rates at 13% in mid-shaft hypospadias and up to 37% in proximal shaft, depending on single or two layer closure and whether polyglactin or chromic was used.\(^11\) The two stage procedure was popularized by Bracka,\(^12\) and reports of a gross fistula rate of 5.7% and a stricture rate of 7%. It is worthwhile mentioning that there was no mention of magnification in the Snodgrass series, whereas Bracka does not rely on magnification at all.\(^11,12\) In our series we experienced one stricture and total fistula rate of 8.8%, 5.3% and 13% for one stage and two stage repairs respectively. The stricture was picked up by urethroscopy. Our postoperative follow-up regimen includes review at 1 and 2 weeks postoperatively. They then are reviewed at 3 months, and from then on yearly till 5-6 years of age before discharge. Khan \textit{et al.}\(^13\) reported an increase in complications as a result of lack of magnification and microsurgical instruments. Hypospadias surgery has as steep learning curve, and it is more likely that more complications will be encountered earlier on in practice.\(^14\)

**Figure 5:** Algorithm for choice of repair.
In conclusion, hypospadias surgery is practiced by a few surgical sub-specialities. It has been practiced for a long time and has evolved remarkably. There is a plethora of techniques and complication rates are still considered relatively high. Strategically approaching hypospadias with this simple algorithm and utilizing the microsurgical instruments with a surgical microscope will help in performing meticulous repairs. This approach will be much appreciated by those embarking in a career of hypospadiology.
