INTRODUCTION

Pain management has always been an important part of dental care. With an estimated 30 million people benefited worldwide, non-steroidal anti-inflammatory drugs (NSAIDs) are the most commonly used drugs for managing surgical pain and inflammation. Consistently, NSAIDs are routinely prescribed for mild to moderate dental pain and will be supplemented/replaced by opioid analgesics in severe pain. The role of steroids as adjunctive measures to reduce postoperative inflammation, swelling, and pain has also received importance in recent years.\[^{1-4}\]

Despite adherence to all surgical recommendations and precautions during dental implant surgery in a normal healthy patient, many patients experience mild to moderate pain and inflammation after the procedure.\[^{5,6}\]

A comprehensive search of commonly used electronic databases such as PubMed and Google Scholar, using the key words “analgesics”, “anti-inflammatory” and “oral implants” was done. Published literature in this context related either to the use of analgesic or anti-inflammatory

ABSTRACT

Aim: This study was conducted to determine the preferred analgesic and anti-inflammatory drugs prescribed by oral implantologists in India. Methods: A structured questionnaire was distributed to 332 dentists to gather information regarding their prescription habits for analgesics and anti-inflammatory drugs. Frequency distributions were computed by type of drug being prescribed and the protocol followed. Results: Analysis of data showed that majority of dentists (85.8%, n = 285) prescribed conventional non-steroidal anti-inflammatory drugs (NSAIDs) for implant surgery. The most common prescription was ibuprofen with paracetamol combination (32.2%, n = 107) followed by diclofenac (20.2%, n = 67). Most dentists reported prescribing different NSAIDs for the same procedure in different patients (64.7%, n = 215). Only, 35.5% (n = 118) followed the peri-operative protocol. Adjunctive prescription of steroids was done by only 33.7% (n = 112). Conclusion: Our study illustrates that the general trend of analgesic and anti-inflammatory drug prescription for dental implant surgery among Indian dentists is mostly in accordance with the guidelines for pain management worldwide. However, it is noteworthy that a few dentists do prescribe drugs not primarily indicated for dental pain management and use widely varying protocols for the same. Therefore, in order to avoid potential complications, it is essential to raise awareness among the dental practitioners of the appropriate indications and dosage regimen of specific drugs.

Key words: Dental implants, non-steroidal anti-inflammatory drugs prescription, steroid, protocol
drugs by dental practitioners in routine clinical practice, with no specific relation to oral implant surgery.

Although the role of NSAIDs and steroids has been very beneficial in terms of pain relief, these drugs also have an associated risk of side effects and adverse drug reactions.[3] Since safe usage of drugs in clinical practice entails maximizing the therapeutic efficacy and minimizing the adverse effects, it is important to gain knowledge of the pattern of use of these widely prescribed drugs by dentists in order to minimize the possible risks associated with these drugs.[14] The aim of our study was therefore to assess the prescription pattern of analgesics and anti-inflammatory drugs during routine oral implant surgery in normal healthy patients among Indian dentists. To our knowledge, this is the first study of its kind to be conducted in the Indian subcontinent.

METHODS

A structured questionnaire was developed to elicit prescription preferences regarding analgesics and anti-inflammatory drugs prescribed for routine oral implant surgery in the normal healthy patients and the protocol(s) followed. Dental surgeons were personally approached at various national events such as conferences and academic meetings and requested to provide the required information. Inclusion criteria for the study sample consisted of dental surgeons performing oral implant surgery and were willing to voluntarily complete the questionnaire. All data was manually transferred from the survey forms to an electronic spreadsheet for further analysis.

RESULTS

Out of a total of 332 dentists that responded to the survey, all study participants stated that they prescribed analgesic and anti-inflammatory drugs for implant surgery to their patients. Nine NSAIDs, acetaminophen (paracetamol) and two semi-synthetic opioid drugs were prescribed [Table 1]. Additionally, 33.7% (n = 112) participants prescribed steroids in conjunction with NSAIDs [Table 2].

The most preferred prescription was the combination of ibuprofen and paracetamol (32.2%, n = 107) [Figure 1]. The most commonly prescribed drugs were ibuprofen (44.3%, n = 147) and diclofenac (33.7%, n = 112). Paracetamol was prescribed by 54.2% (n = 180) of the dentists, however, all of these dentists prescribed paracetamol

as an additional drug in combination with some other analgesic, and in no case was paracetamol used as an analgesic-anti-inflammatory drug alone.

More than half of the dentists prescribed more than one drug (64.7%, n = 215), and of these 8.4% (n = 28) simply stated that they prescribed NSAIDs, without specifying any drug or trade name. Also, majority (56.9%, n = 189) used generic drugs names in their prescriptions, brand name was used by 37.3% (n = 124) and 5.7% mentioned both (n = 19). A single NSAID drug was prescribed by only 35.2% (n = 117) dentists. Unrelated drugs were mentioned by 27.4% (n = 91) dentists and 58.1% (n = 193) indicated the use of pre-formulated drug combinations.

The use of semi-synthetic opioids was noted by 9.0% (n = 30) dentists. Tramadol alone was prescribed by 3.3% (n = 11) dentists while 1.5% (n = 5) gave it in combination with paracetamol. Dextropropoxyphene was prescribed by 1.5% (n = 5) dentists only and it was part of a pre-formulated commercially available drug formulation.

Additional drugs were also prescribed along with analgesic-anti-inflammatory drugs. These included tissue enzymes such as serratiopeptidase (10.8%, n = 36), chymotrypsin (0.3%, n = 1) and chlorzoxazone (4.2%, n = 14). Caffeine was present in 1.5% (n = 5) of the prescriptions. All of these drugs were part of pre-formulated commercially available drug formulations.

Drug dose was mentioned by 5.4% (n = 18) dentists only. The peri-operative treatment protocol (pre-surgical dose followed by post surgical regimen) was preferred by 35.5% (n = 118) dentists while 64.7% (n = 215) gave the medication postoperatively only. The term ‘Stat on Symptoms’ was also mentioned by 21.6% (n = 72) dentists. Post-operative prescription duration ranged from 0 to 9 days, the most common being 5 days.

The oral route was recommended by all 332 dentists with an additional injection via intramuscular route (3.0%, n = 10) or intravenous route (1.5%, n = 5) along with this.

Regarding steroids, out of the 33.7% (n = 112) participants that prescribed steroids, dexamethasone (50.8%, n = 57) was the most preferred, followed by prednisolone (29.4%, n = 33). Also, majority used generic names in their prescription (72.3%, n = 81) but only 19.6% (n = 22) mentioned the dose. It is notable that most dentists preferred injectable steroid therapy (58.9%, n = 66) [Table 2].

**DISCUSSION**

A review of our study results shows that most of the dentists prescribed traditional NSAIDs to patients undergoing routine dental implant surgery. Only a marginal section of the dentists prescribed the newer cyclo-oxygenase selective group of drugs on a regular basis. Similar prescription patterns for analgesics in the dental setting have also been observed in studies conducted in Istanbul,[9] Bangladesh,[10] Karnataka[11] and Alabama.[12] It is noteworthy that analogous results have also been reported in a study illustrating country comparisons in analgesic usage.[13]

Evaluation of the prescription patterns revealed that there was a great deal of variability in the drugs prescribed and the protocols followed for their prescription. Regarding the analgesic drug prescribed, ibuprofen was the most prescribed, followed by diclofenac. The role of both these drugs in the management of dental and post-surgical inflammatory pain is recommended by many authors.[14-17] Amongst recommendations regarding the use of NSAIDs in dentistry, it has been suggested that ibuprofen is an ideal prototype for consideration in pain of dental origin.[21]

A noteworthy aspect of our study was the finding that the most common prescription pattern was the use of ibuprofen in combination with paracetamol, and diclofenac with paracetamol. No dentist prescribed paracetamol alone as an analgesic drug. Guidelines on sedation and management of dental pain[16] state that it is irrational to combine two or more NSAIDs in therapy, however, paracetamol or opioid analgesics are suitable for combination with NSAIDs whenever a combination is required in severe pain only.[18-21] A review of literature related to ibuprofen-paracetamol combination shows that the two drugs tend to provide efficacious pain control in the dental model when used together.[22]

Additionally, our study participants have also prescribed a variety of other NSAIDs such as piroxicam and ketorolac. However, it may be noted that these drugs have not been recommended for pain control in the dental pain model and are known to have more severe side effects.[23-26] Some dentists have also mentioned the use of unrelated NSAIDs in their prescriptions, indicating a subjective preference in describing different drugs to different patients.

Another matter for concern regarding the use of NSAIDs for analgesia is the incidence of side effects, specifically gastrointestinal (GI) bleeding.[23] The safest drug in this regard has been noted as Ibuprofen.[24] However, this has also been related to the frequency and duration of overall NSAID therapy. This may not be significant in normal healthy individuals taking short-term therapy for oral surgical related pain.[24, 23]
In relation to prescription patterns, there was some variability in the preference for perioperative regimens versus postoperative prescription only. The role of a preoperative or loading dose of analgesic medication before surgery has been recommended as a form of preemptive analgesia. In our study, only 35.5% (n = 118) of our participants who preferred the peri-operative regimen gave due consideration to this method of analgesic prescription.

The duration of prescription ranged from a self-medication preference or "stat-on-symptoms" approach to the medication being prescribed for 2 to 9 days post-surgically. Most authors recommend prescription duration of 4 to 6 days, and most of our study participants also fell into this range. All dentists in our study recommended the oral route of delivery, while only a few used an additional injection of NSAID drugs. Again, most authors recommend only oral NSAID therapy for dental and postoperative pain.

When considering the method of prescription, it was seen that fewer dentists wrote the brand names of the drugs prescribed. The majority preferred to use generic names of commercially available drugs, including pre-formulated drug combinations.

To manage NSAIDs associated adverse effects on the GI tract, a proton pump inhibitor or H2 receptor antagonist is usually recommended for patients that are at high risk of ulcers. Only five of our study participants mentioned these drugs in their prescriptions. Our study also illustrated that only a minority prescribed semi-synthetic opioid analgesics (tramadol and dextropropoxyphene) and this trend was also in accordance with indications for use of NSAIDs for dental and post-surgical pain.

The role of glucocorticoids as adjuncts for pain and edema has received interest in recent times. Literature has shown that the short-term use of corticosteroids is safe and provides analgesia in acute postoperative pain in healthy adults. However, the optimal dose, mode and timing of administration remain unclear. One meta-analysis has provided reliable evidence that dexamethasone is an ideal drug for ameliorating acute postoperative pain. Of the 30% of our study sample that did prescribe steroids, the majority did prescribe dexamethasone, but the duration, mode of delivery and protocol were variable. It is noteworthy that many of the dentists in our study prescribed injectable steroid therapy for up to seven days postoperatively.

It was interesting to note that pre-formulated commercially available drug combinations contained additional drugs such as serratopipetidase and chloroxazone. The role of a muscle relaxant in dental implant surgery remains unclear.

Review of current literature reveals that almost all authors are in favour of the use of conventional NSAIDs, specifically ibuprofen, ibuprofen with paracetamol and diclofenac, for the management of dental and postoperative pain and inflammation. These drugs are also easily available over the counter without prescription. The role of steroids, especially dexamethasone, as adjuncts in postoperative pain management has also been reviewed. NSAIDs are also associated with side effects such as GI bleeding and allergic reactions, and it is critical that these drugs be prescribed cautiously.

Our study illustrates that the current trend of prescription of analgesic and anti-inflammatory drugs for routine oral implant surgery among Indian dentists is in accordance with the guidelines for management of dental pain worldwide. However, evidence of prescription of drugs not primarily indicated for dental pain management and protocols not consistent with current recommendations, is noteworthy. It is essential that, to ensure safe delivery and avoidance of potential complications arising due to these drugs, dental practitioners should be more aware of the appropriate dose, dosage regimen and indications for specific analgesics. Additionally, further research is required to assess the outcomes, including adverse effects, related to the prescription of these drugs for oral implant surgery.
